5 Fig. 6-10 shows a spacer located on the structure of MOS transistor.

Since the step coverage capability of TEOS-SiO₂ is excellent, a SiO₂ LPCVD reaction mainly using TEOS has been widely adopted in the semiconductor industry, such the space shown in Fig. 6-10. Since the metal layer used as a contact is not
 10 deposited yet while the spacer is formed, the reaction temperature in (6-18) does not have great influence on the process forming the device or on other properties of the device, such as the distribution of dopant. However, after the deposition of metal is performed, the reaction temperature required in equation (6-18) will limit the application of SiO₂ LPCVD using TEOS, and in stead, a plasma CVD of SiO₂ featured
 15 in the temperature less than 400°C will be used (regarding the fabrication of the space shown in Fig. 6-10, please refer to Section 11-2-2).

The plasma CVD is meant to use plasma to decompose the reaction gas molecule participating in the CVD reaction into atoms, ions or radicals, thereby performing a CVD film deposition technique under a relatively low temperature by the
 20 deposition reaction. Equation (6-19) lists a PECVD reaction⁽¹⁴⁾ using SiH₄ and N₂O as the reaction gas, wherein the fundamental operation conditions and the properties of PECVD SiO₂ are listed in Table 6-1. Since the reaction gas molecule participating in the reaction contains hydrogen atoms and nitrogen atoms, the SiO₂ film formed by PECVD will contain H and N, wherein the content of H is particularly apparent, which

is generally in the range of about 2-9 atomic %⁽¹⁵⁾. Basically, the aforementioned content is closely related to the reaction temperature, RF power and the flow ratio of N₂O vs. SiH₄, and has an effect on the density⁽¹⁵⁾⁽¹⁶⁾ of PECVD SiO₂ film.
